Submitted February 13, 2018 / Accepted August 12, 2018

Abstract. This article presents new exact expressions, written in terms of elementary transcendental functions, for calculating the bit error probability of M-ary Quadrature Amplitude Modulation (M-QAM) scheme considering the wireless communication channel modeled by a Markov chain with N states. For the numerical evaluation of the expressions obtained, a particular case of a Markov chain with two states is considered, with each state representing distinct scenarios. In the first scenario it is considered the presence of Gated Additive White Gaussian Noise (GAWGN) and fading η-µ or κ-µ, while the second scenario considers the presence of the Double Gated Additive White Gaussian Noise (G2AWGN) and fading η-µ or κ-µ. Bit error probability curves as a function of the signal-to-permanent-noise ratio for different values of the signal-to-impulsive-noise ratio, fading parameters and modulation order M are also presented.

Keywords
Markov chains, η-µ fading, κ-µ fading, bit error probability, impulsive noise

1. Introduction

The signal transmitted in industrial environments and indoor environments, such as shopping malls, is subjected to noise from multiple sources and interference in the spectrum band intended for industrial applications in 2.4 GHz [1]. Beyond the noise usually modeled as an additive white Gaussian process, these environments also present noise of impulsive nature that arise mainly due to the presence of numerous thyristorized equipment whose switching can generate disturbances in the wireless links. Electric motors, frequency inverters, welding equipment, triggering of lamps, among others, are examples of sources of impulsive noise [2].

Another challenge commonly encountered in industrial environments is fading, which imposes random variations of intensity on the transmitted signal [1]. This phenomenon arises due to the large number of objects and machines present in these environments, which are usually constructed with metallic materials and provide appropriate conditions to multipath propagation [3]. The combination of phenomena such as impulsive noise and fading can seriously compromise the quality of the communication link.

In such wireless environments, the effects of fading and impulsive noise on the observed signal at the output of a matched filter in the receiver may be modeled by a two-term composition, one representing the information signal affected by fading and the other term representing the impulsive noise [2].

In non selective frequency channel models, fading is usually considered flat and characterized by a single probability distribution over at least one symbol time [4]. However, in environments such as shopping malls and factories, a single probability distribution may not be able to appropriately model the intensity variations imposed on the transmitted signal as the receiver moves and may experience different environmental conditions for multipath propagation. In [2] industrial environments are considered and more than one probability distribution is used to characterize the effects of fading.

A possible way to model sudden changes in the statistical behavior of the transmitted signal intensity, as the receiver moves through the communication environment, is by means of Markov chains [5–7]. One advantage of considering Markov chains, compared to the non selective frequency model, is that they allow to better describe the statistical changes of fading over time [8]. These variations can be caused by changes in the scenarios in which the transmissions are performed and can affect both up and downlinks on reduced-diameter cells as well as horizontal device-to-device links [9].
Other authors have also used Markov chains to describe statistical behavior change in the channel, such as Liu et al. [10] and Altinel and Kurt [11]. Lutz et al. [12], for example, defined a channel model with two states, one classified as good and the other classified as bad, depending on the conditions and level of attenuation in each scenario. Another important work is that of Vucetic and Du [13], which characterized the wireless channel of a particular geographical area of Australia by a Markov chain of four states, combining four different types of conditions.

In this work, exact expressions for the computation of the average bit error probability (BEP), $P_e$, of $M$-ary Quadrature Amplitude Modulation ($M$-QAM) scheme are determined considering that the alternations in the fading statistics along the channel are described by the state transitions of a Markov chain with $N$ states. The expressions obtained are novel and written in terms of elementary transcendental functions. For the numerical evaluation of the expressions obtained, a particular case of a Markov chain with two states is considered, with each state representing distinct scenarios. In the first state of the chain, the presence of the Double Gated Additive White Gaussian Noise (GAWGN) and fading $\eta_\mu$ or $\kappa_\mu$ is considered, whereas in the second state the presence of the Double Gated Additive White Gaussian Noise (G$^2$AWGN) and fading $\eta_\mu$ or $\kappa_\mu$ is considered. In the mathematical characterization of the impulsive noise, we have considered the models GAWGN and G$^2$AWGN because they are able to characterize, respectively, the occurrence of noisy pulses and bursts of noisy pulses. By its turn, the fading is characterized by the distributions $\eta_\mu$ and $\kappa_\mu$, which are generalist models of fading and encompass, as special cases, the distributions of Rayleigh, Rice and Nakagami, among others, and may be used to characterize fading on a small and large scale, with or without line-of-sight [14].

The methodology used to determine $P_e$ is to weight the BEP of the scheme $M$-QAM under the composite noise models GAWGN and G$^2$AWGN by the probability density function (PDF) of the fading envelope. In this approach, the representation of Craig [15] is used for the function $Q(.)$, expressing $P_e$ for an integral defined in the range of 0 to $\pi/2$, in terms of the Moment Generating Function (MGF) of the distributions $\eta_\mu$ and $\kappa_\mu$.

2. Noise Model

The mathematical model of noise $\eta(t)$ is given by [16]

$$\eta(t) = \eta_\mu(t) + C(t)\eta_\mu(t),$$

in which $\eta_\mu(t)$ represents a zero-mean complex white Gaussian random process with variance $\sigma^2_\mu$. $C(t)$ is a signal which models the occurrence of noise $\eta_\mu(t)$, characterized by a continuous time and discrete Bernoulli random process, and $\eta_\mu(t)$ is the background Gaussian noise with zero-mean and variance $\sigma^2_\mu$. The product $C(t)\eta_\mu(t)$, referred to as impulsive noise, in (1), characterizes the noise $\eta(t)$ gated by the process $C(t)$. The noise can be simple or double gated.

In simple gated noise, the noise is referred to as Gated Additive White Gaussian Noise (GAWGN) and the amplitude of $C(t)$ assumes values zero or one randomly, with probabilities $1 - p$ and $p$, respectively. The signal $C(t)$ has unit amplitude in the interval $-a_\mu T/2 \leq t \leq a_\mu T/2$ and zero otherwise. The variable $a_\mu$ can assume values between zero and one.

In double gated noise, the noise is referred to as Double Gated Additive White Gaussian Noise (G$^2$AWGN) and the random signal $C(t)$ is characterized by the product of two auxiliary processes, $C_1(t)$ and $C_2(t)$, that take values in the discrete set $\{0, 1\}$. In the intervals at which $C_1(t)$ assumes value one, several noisy pulses, modeled as $C_2(t)\eta_\mu(t)$, can occur. One can say that the interval for which $C_1(t) = 1$ is a burst of noisy pulses $C_2(t)\eta_\mu(t)$. The product $C_1(t)C_2(t)$ models the occurrence of bursts of noisy pulses. The function $C_1(t)$ assumes the values one and zero with probabilities $p_1$ and $1 - p_1$, respectively. This function has unit amplitude in the interval $0 \leq t \leq \beta T_1$ and zero otherwise. The signal $C_2(t)$ assumes the values one and zero randomly, with probabilities $p_2$ and $1 - p_2$, respectively, and has unit amplitude in the interval $0 \leq t \leq \alpha p_2 T_2$ and zero otherwise. The variables $\beta \leq \alpha p_2$ assume values between zero and one.

3. Average Bit Error Probability of $M$-QAM Under Noise and Fading Modeled by Using a $N$ States Markov Chain

It was shown in [17] that the BEP of $M$-QAM for a given fading $z$, denoted by $P(e|z)$, under GAWGN, can be written as

$$P(e|z) = \frac{2}{M \log_2 \sqrt{M}} \sum_{k=1}^{\log_2 \sqrt{M}} \sum_{i=0}^{(i-2+\sqrt{i})} w(i, k, M) \times \left( a_p Q \left( \sqrt{\frac{(a(i, M))^{2} \delta g^2}{\delta g + \delta_i}} \right) + (1 - a_p) Q \left( \sqrt{\frac{(a(i, M))^{2} \delta g^2}{\delta g + \delta_i}} \right) \right),$$

in which

$$w(i, k, M) = (-1)^{\left\lfloor \frac{k+1}{M} \right\rfloor} \cdot \left( 2^{k-1} - \left[ \frac{i \cdot 2^{k-1}}{\sqrt{M}} + \frac{1}{2} \right] \right),$$

$$a(i, M) = \frac{3(2i + 1)^2}{(M - 1) \log_2 M},$$

$M$ is the order of the constellation, $\delta g$ is the signal-to-permanent-noise ratio, defined as the ratio of the signal power to the power of the background Gaussian noise that always presents in the system, and $\delta_i$ is the signal-to-impulsive-noise ratio, defined as the ratio between the power of the signal and the power of the impulsive noise that acts in the system.
Making \( x = z^2 \) \hfill (5)

in (2), \( P(e|z) \) can be written as

\[
P(e|z) = \frac{2}{\sqrt{M \log_2 M}} \sum_{k=1}^{\log_2 M} \sum_{j=0}^{(1-2^k) \sqrt{M} - 1} w(i, k, M) \times \left\{ \alpha_p P Q \left( \frac{a(i, M) x \delta_g \delta_i}{\delta_g + \delta_i} \right) + (1 - \alpha_p) P \right\}.
\]

The bit error probability, \( P_e \), can be obtained by taking the average of (6) with respect to the PDF of \( x \), that is,

\[
P_e = \int_0^\infty P(e|x) f_X(x) \, dx = \frac{2}{\sqrt{M \log_2 M}} \sum_{k=1}^{\log_2 M} \sum_{j=0}^{(1-2^k) \sqrt{M} - 1} w(i, k, M) \times \left\{ \alpha_p \int_0^\infty Q \left( \frac{a(i, M) x \delta_g \delta_i}{\delta_g + \delta_i} \right) f_X(x) \, dx + (1 - \alpha_p) \int_0^\infty Q \left( \frac{a(i, M) x \delta_g \delta_i}{\delta_g + \delta_i} \right) f_X(x) \, dx \right\},
\]

in which \( f_X(x) \) is the PDF of the fading.

An alternative expression for the function \( Q(\cdot) \) is given by [15]

\[
Q(x) = \frac{1}{\pi} \int_{-\infty}^{\infty} \exp \left( -\frac{x^2}{2 \sin^2 \theta} \right) \, d\theta.
\]

Thus, \( P_e \) can be written as

\[
P_e = \frac{2}{\pi \sqrt{M \log_2 M}} \sum_{k=1}^{\log_2 M} \sum_{j=0}^{(1-2^k) \sqrt{M} - 1} w(i, k, M) \times \left\{ \alpha_p \int_0^\infty \int_0^{\frac{\pi}{2}} \exp \left( -\frac{a(i, M) x \delta_g \delta_i}{2 \sin^2 \theta (\delta_g + \delta_i)} \right) f_X(x) \, dx \, d\theta + (1 - \alpha_p) \int_0^\infty \int_0^{\frac{\pi}{2}} \exp \left( -\frac{a(i, M) x \delta_g \delta_i}{2 \sin^2 \theta (\delta_g + \delta_i)} \right) f_X(x) \, dx \, d\theta \right\}.
\]

Since the fading is constant for at least one symbol interval \( T_e \), it is possible to represent the behavior of the channel by means of a Markov chain of \( N \) states. In the model considered in this article, whenever the fading changes to a particular state, it is assumed that it will remain in this state for a time \( T_e = kT_s \) seconds. The parameter \( T_s \) is a discrete random variable with distribution \( p_T(t) \) and average value \( \bar{T}_s \). In a given state \( j \), the fading envelope is characterized by a random variable \( X_j \) with probability density function \( f_X(x) \).

Under these conditions, the probability of \( X \leq x \) can be written as

\[
P(X \leq x) = \sum_{i=1}^{N} \sum_{j=1}^{N} P(X \leq x, T_i, e_j) = \sum_{i=1}^{N} \sum_{j=1}^{N} P(X \leq x|T_i, e_j) P(T_i, e_j).
\]

Given that [18]

\[
P(T_i, e_j) = \frac{P(e_j) \bar{T}_i \delta[i-j]}{\sum_{m=1}^{N} \sum_{v=1}^{N} \bar{T}_v P(e_v) \delta[u-v]},
\]

where \( \delta[i-j] \) is the Kronecker delta, which assumes value equal to one if \( i = j \) and zero otherwise; \( \bar{T}_i \) is the average duration of the \( i \)-th state and \( P(e_j) \) is the probability that the chain be in the \( j \)-th state after \( n \) transitions, it follows that

\[
P(X \leq x) = \sum_{i=1}^{N} \sum_{j=1}^{N} P(X \leq x|T_i, e_j)
\]

\[
\times \frac{P(e_j) \bar{T}_i \delta[i-j]}{\sum_{m=1}^{N} \sum_{v=1}^{N} \bar{T}_v P(e_v) \delta[u-v]}
\]

\[
= \sum_{j=1}^{N} P(X \leq x|T_j, e_j)
\]

\[
= \sum_{j=1}^{N} P(X \leq x) \frac{P(e_j) \bar{T}_j}{\sum_{v=1}^{N} \bar{T}_v P(e_v)}.
\]

Hence, the probability density function \( f_X(x) \) is obtained from the derivative of the cumulative distribution function \( F_X(x) = P(X \leq x) \) and can be written as

\[
f_X(x) = \sum_{j=1}^{N} f_{X_j}(x) \frac{P(e_j) \bar{T}_j}{\sum_{v=1}^{N} \bar{T}_v P(e_v)}.
\]

in which \( f_{X_j}(x) \) is the PDF of \( X \) in the \( j \)-th state of the Markov chain.

A simplification of this model can be performed considering that the chain remains in a certain state during a symbol interval and then performs a transition to another state. This means that all states have the same average duration value, since fading can be considered independent of time for at least one symbol interval \( T_e \). Considering a Markov chain of \( N \) states, the probability of \( X \leq x \) can be written as

\[
P(X \leq x) = \sum_{j=1}^{N} P(X \leq x, e_j)
\]

\[
= \sum_{j=1}^{N} P(X \leq x|e_j) P(e_j)
\]

\[
= \sum_{j=1}^{N} P(X_j \leq x) P(e_j).
\]
Hence, the PDF $f_X(x)$ is given by
\[
f_X(x) = \sum_{j=1}^{N} f_{X_j}(x) P(e_j),
\]
in which $f_{X_j}(x)$ is the PDF of $X$ in the $j$-th state of the Markov chain and $P(e_j)$ is the probability that the chain be in the $j$-th state.

Substituting (15) in (9), it follows that
\[
P(e_j) \times \left( \alpha_p P \int_0^\infty \int_0^\infty \exp \left( -\frac{a(i, M)x}{2 \sin^2 \theta} \delta_g \delta_i \right) f_{X_j}(x) dx d\theta \right) \\
+ \left(1 - \alpha_p P \right) \int_0^\infty \int_0^\infty \exp \left( -\frac{a(i, M)x}{2 \sin^2 \theta} \delta_g \right) f_{X_j}(x) dx d\theta 
\]
(16)

Given that [19]
\[
\int_0^\infty e^{-x} f_X(x) dx = M_X(s),
\]
in which $M_X(s)$ represents the MGF of $f_X(x)$, it follows that it is possible to write (16) as
\[
P(e) = \frac{2}{\pi \sqrt{M \log_2 M}} \sum_{k=1}^{\log_2 M (1-2^k) \sqrt{M}} \sum_{i=0}^{N} \sum_{j=1}^{N} w(i, k, M) \\
\times P(e_j) \left( \alpha_p P \int_0^\infty \int_0^\infty M_{X_j} \left( \frac{a(i, M) \delta_g \delta_i}{2 \sin^2 \theta \delta_g + \delta_i} \right) d\theta \right) \\
+ \left(1 - \alpha_p P \right) \int_0^\infty \int_0^\infty M_{X_j} \left( \frac{a(i, M) \delta_g}{2 \sin^2 \theta} \right) d\theta 
\]
(17)

Using (5), it follows that $P(e|z = \sqrt{x})$ is given by
\[
P(e|z = \sqrt{x}) = \frac{2}{\sqrt{M \log_2 M}} \sum_{k=1}^{\log_2 M (1-2^k) \sqrt{M}} \sum_{i=0}^{N} \sum_{j=1}^{N} w(i, k, M) \\
\times \left( \alpha_p \beta \beta_1 p_2 Q \left( \frac{a(i, M) \sqrt{2 \delta_g \delta_i}}{\delta_g + \delta_i} \right) \right) \\
+ \left(1 - \alpha_p \beta \beta_1 p_2 \right) Q \left( \frac{a(i, M) \sqrt{2 \delta_g}}{\delta_g} \right) 
\]
(20)

The average bit error probability for a Markov chain with $N$ states for the G$^2$AWGN model is given by
\[
P(e) = \frac{2}{\pi \sqrt{M \log_2 M}} \sum_{k=1}^{\log_2 M (1-2^k) \sqrt{M}} \sum_{i=0}^{N} \sum_{j=1}^{N} w(i, k, M) \\
\times P(e_j) \left( \alpha_p \beta \beta_1 p_2 \int_0^\infty \int_0^\infty M_{X_j} \left( \frac{a(i, M) \delta_g \delta_i}{2 \sin^2 \theta \delta_g + \delta_i} \right) d\theta \right) \\
+ \left(1 - \alpha_p \beta \beta_1 p_2 \right) \int_0^\infty \int_0^\infty M_{X_j} \left( \frac{a(i, M) \delta_g}{2 \sin^2 \theta \delta_g} \right) d\theta 
\]
(21)
in which $M_X(\cdot)$ represents the MGF.

4. Moment Generating Function of the Distributions $\eta$-$\mu$ and $\kappa$-$\mu$

If $z$ in (2) and (19) has distribution $\eta$-$\mu$ or $\kappa$-$\mu$, the probability density function of $x = z^2$, in (6) and (20), is given by [19]
\[
f_X(x) = \frac{1}{2 \sqrt{x}} \left[ f_{\sqrt{x}}(\sqrt{x}) + f_{-\sqrt{x}}(-\sqrt{x}) \right].
\]
(22)

If $z$ has distribution $\eta$-$\mu$, it follows that $f_X(x)$ is given by
\[
f_{X_{\eta, \mu}}(x) = 2 \sqrt{\pi} u^{0.5} h_\mu \chi_{\mu+0.5} \exp \left( - \frac{2 \mu h x}{\Omega} \right) \\
\times I_{\mu-0.5} \left( \frac{2 \mu h x}{\Omega} \right) u(x),
\]
(23)
in which $u(\cdot)$ represents the unit step function, $\Omega$ if the average power of the signal, $\Gamma(\cdot)$ represents the Gamma function and the parameters $H$ and $h$ are given by
\[
H = \frac{\eta^{-1} - \eta}{4} \quad \text{and} \quad h = \frac{2 + \eta^{-1} + \eta}{4}
\]
(24)
for the first format and $\eta, 0 < \eta < \infty$, is the ratio of the power of the phase and quadrature components. The generalized moment of that distribution is given by [20]
\[
M_{X_{\eta, \mu}}(s) = \left( \frac{4 \mu^2 h}{(2h - H) \mu + s \Omega)(2h + H) \mu + s \Omega} \right)^\mu.
\]
(25)
If $z$ has distribution $\kappa-\mu$, it follows that $f_X(x)$ is given by

$$f_{X_{\kappa-\mu}}(x) = \frac{\mu(1 + \kappa)}{\kappa \exp(\frac{x}{\kappa}) ^ \frac{\alpha}{\mu} \exp\left(-\frac{\mu(1 + \kappa)x}{\Omega}\right)} \times 1_{y-1} \left(2^{\mu(1(1 + \kappa)x)} \right) u(x), \quad (26)$$

in which the parameter $\kappa$ is the ratio of the total power of the dominant components and the power of the scattered waves, and $\Omega$ is the average power of the signal. The generalized moment for the distribution $\kappa-\mu$ is given by [20]

$$M_{X_{\kappa-\mu}}(s) = \left(\frac{\mu(1 + \kappa)}{\kappa \mu(1 + \kappa) + s \Omega}\right)^\mu \exp\left(\frac{\mu^2 \kappa(1 + \kappa)}{\mu(1 + \kappa) + s \Omega} - \mu \kappa\right). \quad (27)$$

5. Results

Simulations were carried out considering two channel scenarios. The first scenario is characterized by the occurrence of GAWGN noise and fading that can alternate between the models $\eta-\mu$ and $\kappa-\mu$, and the second scenario is characterized by the presence of noise $G^2$ AWGN and fading $\eta-\mu$ or $\kappa-\mu$.

The values adopted for the Markov chain parameters are based on the work of Sanchez-Salas and Cuevas-Ruiz [8]. The values used for the parameters of the impulse noise $\eta(t)$ and the modulation schemes are chosen in accordance with impulse interference studies described in [21] and with the conditions of simulations performed in [16].

In the present work, simulations were carried out by Monte Carlo method, considering $5 \times 10^6$ transmitted bits. In the simulations, the matrix of transition probabilities between states is given by [8]

$$P = \begin{bmatrix} 0.7 & 0.3 \\ 0.1 & 0.9 \end{bmatrix}. \quad (28)$$

initially the states are equiprobable and the steady state is obtained with a high number of transitions between states. The absence or presence of line of sight between transmitter and receiver is characterized by $\eta-\mu$ or $\kappa-\mu$ distribution, resp.

The average bit error probability curves of 64-QAM, for a Markov chain with two states, under the effects of noise GAWGN and $\eta-\mu$ or $\kappa-\mu$ fading are presented in Fig. 1. The curves are plotted as a function of the signal-to-permanent-noise ratio, $\delta_\eta$, for different values of $\delta_\eta$, with $p = 0.3$, $\mu = 2.0$, $\Omega = 1.0$, $\kappa = 2.0$, $\eta = 0.3$, and $\alpha_p = 0.1$. For low values of signal-to-impulsive-noise ratio, with $\delta_\eta =$ 1 dB and $\delta_\eta =$ 10 dB, it is observed that the average bit error probability, $P_e$, changes little with the increase of $\delta_\eta$, for values of signal-to-permanent-noise ratio in the range 20–40 dB. For the four values of $\delta_\eta$ under consideration, it is observed, for $\delta_\eta$ in the range 0 to 12 dB, that the average bit error probability curves overlap. Figure 1 also presents the theoretical $P_e$ curve with the Markov chain subjected to AWGN and fading $\eta-\mu$ or $\kappa-\mu$. It is observed that the curves with the presence of impulsive noise have a higher $P_e$ value when compared to the theoretical curve of $P_e$ with the communication channel under the effect of AWGN. It is important to observe that the AWGN theoretical curve can be seen as a lower bound of the system performance.

It is also observed in Fig. 1 that the average $P_e$ curves tend to become irreducible from a given signal-to-permanent-noise ratio. For low values $\delta_\eta$, such as 1 dB, one has, for $\delta_\eta =$ 20 dB, that the power of the impulsive noise is approximately 80 times greater than the power of the permanent noise, contributing so that the average $P_e$ does not decrease from a given value of $\delta_\eta$. For high values of signal-to-impulsive-noise ratio, such as 20 dB, both permanent and impulsive noise have low power. This explains why the respective average $P_e$ curve presents a greater approximation (when compared to the curves referring to the low signal-to-impulsive-noise ratio) to the curve determined by the AWGN noise and $\eta-\mu$ or $\kappa-\mu$ fading. However, even for this case of high $\delta_\eta$, the average $P_e$ also tends to become irreducible from a given value of $\delta_\eta$, because in this scenario the power of the permanent noise is much larger than the power of the impulsive noise. This contributes to the receiver’s decision-making regions becoming more indefinite and, consequently, correct decoding of the transmitted bits is impaired.

In Fig. 2 average bit error probability curves are presented, for different values of the modulation order $M$, for the channel modeled by a Markov chain with two states, under the effects of noise GAWGN and $\eta-\mu$ or $\kappa-\mu$ fading, considering $\mu = 2.0$, $\alpha_p = 0.3$, $p = 0.4$, $\eta = 0.2$, $\kappa = 2.0$, $\Omega = 1.0$ and $\delta_\eta =$ 20 dB. As the parameter $M$ increases, the greater is the number of symbols present in the constellation, and consequently the receiver is more likely to make an incorrect decision. Therefore, in this scenario, for fixed values of signal-to-permanent-noise ratio, it follows that greater average bit error probabilities are obtained. For $\delta_\eta$ ranging from 30 to 40 dB, average bit error probability less than $10^{-5}$ is obtained with $M = 16$. An average bit error probability of $10^{-3}$ is achieved with $\delta_\eta =$ 15.0 dB for $M = 16$ and with $\delta_\eta =$ 26.6 dB for $M = 256$. It is also observed in Fig. 2 that the presence of impulsive noise causes the $P_e$ curves deviate from the curve obtained when only AWGN noise is present in the system.

In Fig. 3 average bit error probability curves of 64-QAM are presented for a Markov chain with two states, under GAWGN and $\eta-\mu$ or $\kappa-\mu$ fading, with $\mu = 2.0$, $\eta = 0.3$, $\Omega = 1.0$, $\alpha_p = 0.1$, $p = 0.2$ and $\delta_\eta =$ 20 dB. The $P_e$ curves are plotted as a function of the signal-to-permanent-noise ratio, $\delta_\eta$, for different values of $\kappa$. One observes in Fig. 3 that greater average bit error probability is obtained as $\kappa$ increases. It is also observed that the $P_e$ curves for the four considered $\kappa$ values tend to decrease faster when noise in the channel is the AWGN. In turn, around $\delta_\eta =$ 20 dB, when the power of the impulsive noise is greater than the power of the permanent AWGN noise, the $P_e$ curves tend to decrease.
slowly when compared to AWGN curves. It is observed that $P_e = 10^{-3}$ is obtained with $\delta_g \approx 17.3$ dB for $\kappa = 0.3$, while it is obtained with $\delta_g \approx 21.1$ dB for $\kappa = 6.3$.

In Fig. 4, average bit error probability curves of 64-QAM are presented, for a Markov chain with two states, under the effects of noise $G^2$AWGN and $\eta$-$\mu$ or $\kappa$-$\mu$ fading, with $\mu = 2.0$, $\kappa = 1.0$, $\Omega = 1.0$, $\eta = 1.5$, $\alpha_p = 0.5$, $p_2 = 0.5$, $\beta = 0.5$ and $p_1 = 0.5$, for four different values of signal-to-impulsive-noise ratio, $\delta_i$. For comparative purposes, the BEP curve is also shown in Fig. 4 when the Markov chain is subjected to AWGN and $\eta$-$\mu$ or $\kappa$-$\mu$ fading. It is observed that the BEP decreases as $\delta_g$ increases, for fixed values of $\delta_i$. As the value of $\delta_i$ increases, it is noted that the BEP curves tend to follow the curve provided for the case where only AWGN noise and fading are present in the channel. In addition, it is observed that values of $P_e$ less than $10^{-3}$ are obtained only with high values of $\delta_i$, such as 20 dB.

Average bit error probability curves for four values of modulation order $M$, for a channel modeled by a Markov chain with two states, subjected to noise $G^2$AWGN and $\eta$-$\mu$ or $\kappa$-$\mu$ fading, are presented in Fig. 5, for $\delta_i = 20$ dB, $\mu = 2.0$, $\kappa = 1.0$, $\Omega = 1.0$, $\eta = 1.5$, $\alpha_p = 0.5$, $p_2 = 0.5$, $\beta = 0.5$ and $p_1 = 0.5$. The greater the number of symbols $M$ in the constellation, the closer the symbols affected by the noise and, consequently, the greater the average bit error probability for a fixed $\delta_g$. An average bit error probability equal to $10^{-3}$ is obtained with $\delta_g \approx 25.3$ dB for $M = 16$ and with $\delta_g \approx 30.3$ dB for $M = 64$. For $\delta_i = 20$ dB, it is observed that the average bit error probability, $P_e$, is not less than $10^{-3}$ for $\delta_g < 40$ dB, for constellations with $M \geq 64$.

In Fig. 6 average bit error probability curves of 64-QAM are presented for a Markov chain with two states, under the effects of noise $G^2$AWGN and $\eta$-$\mu$ or $\kappa$-$\mu$ fading. The curves are plotted as a function of the signal-to-permanent-noise ratio, $\delta_g$, for different values of $\kappa$, with $\mu = 2.0$, $\eta = 1.5$, $\Omega = 1.0$, $\alpha_p = 0.5$, $p_1 = 0.5$, $p_2 = 0.5$ and $\delta_i = 20$ dB. As $\kappa$ increases, a greater bit error probability is obtained. It is observed that an average bit error probability of $10^{-3}$ is obtained with $\delta_g \approx 25.0$ dB for $\kappa = 0.3$, while it is obtained with $\delta_g \approx 33.0$ dB for $\kappa = 6.3$. One observes in Fig. 6, by the dashed lines, that the $P_e$ curves of 64-QAM for a Markov chain with two states under the effects of AWGN and $\eta$-$\mu$ or $\kappa$-$\mu$ fading are practically linear for $\delta_g$ in the range 20–40 dB.

6. Conclusion

This article presents new exact expressions for the average bit error probability, \( P_e \), of the \( M \)-QAM scheme for a wireless communication channel model with fading driven by a Markov chain of \( N \) states. For numerical evaluation of the mathematical expressions, a particular case of Markov chain with two states is considered, each one representing a different fading scenario. In the first state of the chain, the presence of the Gated Additive White Gaussian Noise (GAWGN) and fading \( \eta - \mu \) or \( \kappa - \mu \) is considered, whereas in the second state the presence of the Double Gated Additive White Gaussian Noise (\( G^2 \)AWGN) and fading \( \eta - \mu \) or \( \kappa - \mu \) is considered. Average bit error probability curves under different values of the signal-to-impulsive-noise ratio (\( \delta_i \)), fading parameters and modulation order \( M \) are shown.

In the simulation results, it has been observed that as the constellation order \( M \) increases, the performance of the receiver is worse, and consequently larger values of \( P_e \) are obtained for fixed values of the signal-to-permanent-noise ratio (\( \delta_i \)). Concerning the increase in the signal-to-impulsive-noise ratio, it was observed that some average bit error probability curves remained practically constant at certain intervals with the increase of \( \delta_g \) for \( \delta_i \) equal to 1 dB and 10 dB.

As future works, we aim to determine closed expressions for the average bit error probability of the modulation scheme \( M \)-QAM for a \( N \) states Markov chain under the effects of GAWGN or \( G^2 \)AWGN and \( \alpha - \mu \) fading [22].
